Empirical Methods in Natural Language Processing
Lecture 3
N-gram Language Models

(most slides from Sharon Goldwater; some adapted from Alex Lascarides)

19 January 2023

Recap

- Previously, we talked about corpus data and some of the information we can get from it, like word frequencies.

- For some tasks, like sentiment analysis, word frequencies alone can work pretty well (though can certainly be improved on).

- For other tasks, we need more.

- Today we consider **sentence probabilities**: what are they, why are they useful, and how might we compute them?

Review: Word-based sentiment

- Recall that we can predict sentiment for a document based on counting positive and negative words.

- Do you think the following words would be positive or negative in a movie review?

  - OK
  - Action
  - Star

N-grams

- In some cases, looking at more than one word at a time might be more informative.

  - action movie vs. action packed
  - Star Wars vs. star studded

- An n-**gram** is a word sequence of length n.

  - 1-gram or **unigram**: action
  - 2-gram or **bigram**: action packed
  - 3-gram or **trigram**: action packed adventure
  - 4-gram: action packed adventure film

N-grams

The Force Awakens brings back the Old Trilogy 's heart , humor , mystery , and fun .

How many:

- Unigrams?

- Bigrams?

- Trigrams?

Character N-grams

- A **character n-gram** applies the same idea to characters rather than words.

- E.g. unnatural has character bigrams un, nn, na, . . . , al

- Why might this concept be useful for NLP?

Towards Sentence Probabilities

- "Probability of a sentence" = how likely is it to occur in natural language

  – Consider only a specific language (English)

$$\mathrm{P}(\text{the cat slept peacefully}) > \mathrm{P}(\text{slept the peacefully cat})$$

$$\mathrm{P}(\text{she studies morphosyntax}) > \mathrm{P}(\text{she studies more faux syntax})$$

Language models in NLP

- It's very difficult to know the true probability of an arbitrary sequence of words.

- But we can define a **language model** that will give us good approximations.

- Like all models, language models will be good at capturing some things and less good for others.

  - We might want different models for different tasks.
  - Today, one type of language model: an **N-gram model**.

Spelling correction

Sentence probabilities help decide correct spelling.

mis-spelled text

<p style="color:blue">no much effert</p>

↓   (Error model)

possible outputs

<p style="color:blue">no much effect
so much effort
no much effort
not much effort
...</p>

↓   (Language model)

best-guess output

<p style="color:blue">not much effort</p>

Automatic speech recognition

Sentence probabilities help decide between similar-sounding options.

speech input

    ↓   (Acoustic model)

                                       She studies morphosyntax

possible outputs   She studies more faux syntax

                                       She's studies morph or syntax

                                     ...

    ↓   (Language model)

best-guess output   She studies morphosyntax

Machine translation

Sentence probabilities help decide word choice and word order.

non-English input

        ↓   (Translation model)

                                   She is going home

possible outputs   She is going house

                                   She is traveling to home

                                   To home she is going

                                   ...

        ↓   (Language model)

best-guess output   She is going home

LMs for prediction

- LMs can be used for **prediction** as well as correction.

- Ex: predictive text correction/completion on your mobile phone.

  - Keyboard is tiny, easy to touch a spot slightly off from the letter you meant.
  - Want to correct such errors as you go, and also provide possible completions. Predict as as you are typing: ineff...

- In this case, LM may be defined over sequences of *characters* instead of (or in addition to) sequences of words.

But how to estimate these probabilities?

- We want to know the probability of word sequence $\vec{w} = w_1 \ldots w_n$ occurring in English.

- Assume we have some **training data**: large corpus of general English text.

- We can use this data to **estimate** the probability of $\vec{w}$ (even if we never see it in the corpus!)

Probability theory vs estimation

- Probability theory can solve problems like:

  - I have a jar with 6 blue marbles and 4 red ones.
  - If I choose a marble uniformly at random, what's the probability it's red?

Probability theory vs estimation

- Probability theory can solve problems like:

  - I have a jar with 6 blue marbles and 4 red ones.
  - If I choose a marble uniformly at random, what's the probability it's red?

- But often we don't know the true probabilities, only have data:

  - I have a jar of marbles.
  - I repeatedly choose a marble uniformly at random and then replace it before choosing again.
  - In ten draws, I get 6 blue marbles and 4 red ones.
  - On the next draw, what's the probability I get a red marble?

- The latter also requires estimation theory.

Notation

- I will often omit the random variable in writing probabilities, using $P(x)$ to mean $P(X = x)$.

- When the distinction is important, I will use

  - $P(x)$ for *true* probabilities
  - $\hat{P}(x)$ for *estimated* probabilities
  - $P_{\mathrm{E}}(x)$ for estimated probabilities using a particular estimation method E.

- But since we almost always mean estimated probabilities, may get lazy later and use $P(x)$ for those too.

Example estimation: M&M colors

What is the proportion of each color of M&M?

- In 48 packages, I find[1] 2620 M&Ms, as follows:

Red	Orange	Yellow	Green	Blue	Brown
372	544	369	483	481	371

- How to estimate probability of each color from this data?

---

[1]Actually, data from: https://joshmadison.com/2007/12/02/mms-color-distribution-analysis/

Relative frequency estimation

- Intuitive way to estimate discrete probabilities:

$$P_{\mathrm{RF}}(x) = \frac{C(x)}{N}$$

  where $C(x)$ is the count of x in a large dataset, and
  $N = \sum_{x'} C(x')$ is the total number of items in the dataset.

Relative frequency estimation

- Intuitive way to estimate discrete probabilities:

$$P_{\mathrm{RF}}(x) = \frac{C(x)}{N}$$

  where $C(x)$ is the count of x in a large dataset, and
  $N = \sum_{x'} C(x')$ is the total number of items in the dataset.

- M&M example: $P_{\mathrm{RF}}(\mathrm{red}) = \frac{372}{2620} = .142$

- This method is also known as **maximum-likelihood estimation** (MLE) for reasons we'll get back to.

MLE for sentences?

Can we use MLE to estimate the probability of $\vec{w}$ as a sentence of English? That is, the prob that some sentence S has words $\vec{w}$?

$$P_{\text{MLE}}(S = \vec{w}) = \frac{C(\vec{w})}{N}$$

where $C(\vec{w})$ is the count of $\vec{w}$ in a large dataset, and N is the total number of sentences in the dataset.

Sentences that have never occurred

the Archaeopteryx soared jaggedly amidst foliage

vs

jaggedly trees the on flew

- Neither ever occurred in a corpus (until I wrote these slides).
  $\Rightarrow C(\vec{w}) = 0$ in both cases: MLE assigns both zero probability.

- But one is grammatical (and meaningful), the other not.
  $\Rightarrow$ Using MLE on full sentences doesn't work well for language model estimation.

The problem with MLE

- MLE thinks anything that hasn't occurred will never occur (P=0).

- Clearly not true! Such things can have differering, and non-zero, probabilities:

  - My hair turns blue
  - I injure myself in a skiing accident
  - I travel to Finland

- And similarly for word sequences that have never occurred.

Sparse data

- In fact, even things that occur once or twice in our training data are a problem. Remember these words from Europarl?

  cornflakes, mathematicians, pseudo-rapporteur, lobby-ridden, Lycketoft, UNCITRAL, policyfor, Commissioneris, 145.95

  All occurred once. Is it safe to assume all have equal probability?

- This is a **sparse data** problem: not enough observations to estimate probabilities well. (Unlike the M&Ms, where we had large counts for all colours!)

- For sentences, many (most!) will occur rarely if ever in our training data. So we need to do something smarter.

Towards better LM probabilities

- One way to try to fix the problem: estimate $P(\vec{w})$ by combining the probabilities of smaller parts of the sentence, which will occur more frequently.

- This is the intuition behind **N-gram language models**.

Deriving an N-gram model

- We want to estimate $P(S = w_1 \ldots w_n)$.

    – Ex: $P(S = \text{the cat slept quietly})$.

- This is really a joint probability over the words in S:
  $P(W_1 = \text{the}, W_2 = \text{cat}, W_3 = \text{slept}, \ldots W_4 = \text{quietly})$.

- Concisely, $P(\text{the, cat, slept, quietly})$ or $P(w_1, \ldots w_n)$.

Deriving an N-gram model

- We want to estimate $P(S = w_1 \ldots w_n)$.

  - Ex: $P(S = \text{the cat slept quietly})$.

- This is really a joint probability over the words in S:
  $P(W_1 = \text{the}, W_2 = \text{cat}, W_3 = \text{slept}, \ldots W_4 = \text{quietly})$.

- Concisely, $P(\text{the, cat, slept, quietly})$ or $P(w_1, \ldots w_n)$.

- Recall that for a joint probability, $P(X, Y) = P(Y|X)P(X)$. So,

  $P(\text{the, cat, slept, quietly}) = P(\text{quietly}|\text{the, cat, slept})P(\text{the, cat, slept})$
  $= P(\text{quietly}|\text{the, cat, slept})P(\text{slept}|\text{the, cat})P(\text{the, cat})$
  $= P(\text{quietly}|\text{the, cat, slept})P(\text{slept}|\text{the, cat})P(\text{cat}|\text{the})P(\text{the})$

Deriving an N-gram model

- More generally, the chain rule gives us:

$$P(w_1, \ldots w_n) = \prod_{i=1}^{n} P(w_i | w_1, w_2, \ldots w_{i-1})$$

- But many of these conditional probs are just as sparse!

  - If we want $P(\text{I spent three years before the mast})$...
  - we still need $P(\text{mast}|\text{I spent three years before the})$.

Example due to Alex Lascarides/Henry Thompson

Deriving an N-gram model

- So we make an **independence assumption**: the probability of a word only depends on a fixed number of previous words (**history**).

  - **trigram model**: $P(w_i|w_1, w_2, \dots w_{i-1}) \approx P(w_i|w_{i-2}, w_{i-1})$
  - **bigram model**: $P(w_i|w_1, w_2, \dots w_{i-1}) \approx P(w_i|w_{i-1})$
  - **unigram model**: $P(w_i|w_1, w_2, \dots w_{i-1}) \approx P(w_i)$

- In our example, a trigram model says

  - $P(\text{mast}|\text{I spent three years before the}) \approx P(\text{mast}|\text{before the})$

Trigram independence assumption

- Put another way, trigram model assumes these are all equal:

  - $P(\text{mast}|\text{I spent three years before the})$
  - $P(\text{mast}|\text{I went home before the})$
  - $P(\text{mast}|\text{I saw the sail before the})$
  - $P(\text{mast}|\text{I revised all week before the})$

  because all are estimated as $P(\text{mast}|\text{before the})$

- Also called a **Markov assumption**

Andrey Markov $\rightarrow$

- Not always a good assumption! But it does reduce the sparse data problem.

Estimating trigram conditional probs

- We still need to estimate $P(\text{mast}|\text{before, the})$: the probability of mast given the two-word history before, the.

- If we use relative frequencies (MLE), we consider:

  - Out of all cases where we saw before, the as the first two words of a trigram,
  - how many had mast as the third word?

Estimating trigram conditional probs

- So, in our example, we'd estimate

$$P_{MLE}(\text{mast}|\text{before, the}) = \frac{C(\text{before, the, mast})}{C(\text{before, the})}$$

  where $C(x)$ is the count of x in our training data.

- More generally, for any trigram we have

$$P_{MLE}(w_i|w_{i-2}, w_{i-1}) = \frac{C(w_{i-2}, w_{i-1}, w_i)}{C(w_{i-2}, w_{i-1})}$$

Example from *Moby Dick* corpus

$$C(\textit{before, the}) = 55$$

$$C(\textit{before, the, mast}) = 4$$

$$\frac{C(\textit{before, the, mast})}{C(\textit{before, the})} = 0.0727$$

- *mast* is the second most common word to come after *before the* in *Moby Dick*; *wind* is the most frequent word.

- $P_{MLE}(\textit{mast})$ is 0.00049, and $P_{MLE}(\textit{mast}|\textit{the})$ is 0.0029.

- So seeing *before the* vastly increases the probability of seeing *mast* next.

Trigram model: summary

- To estimate $P(\vec{w})$, use chain rule and make an indep. assumption:

$$P(w_1, \ldots w_n) = \prod_{i=1}^{n} P(w_i | w_1, w_2, \ldots w_{i-1})$$

$$\approx P(w_1) P(w_2 | w_1) \prod_{i=3}^{n} P(w_i | w_{i-2}, w_{i-1})$$

- Then estimate each trigram prob from data (here, using MLE):

$$P_{MLE}(w_i | w_{i-2}, w_{i-1}) = \frac{C(w_{i-2}, w_{i-1}, w_i)}{C(w_{i-2}, w_{i-1})}$$

- On your own: work out the equations for other N-grams (e.g., bigram, unigram).

Practical details (1)

- Trigram model assumes two word history:

$$P(\vec{w}) = P(w_1)P(w_2|w_1) \prod_{i=3}^{n} P(w_i|w_{i-2}, w_{i-1})$$

- But consider these sentences:

	w_1	w_2	w_3	w_4
(1)	he	saw	the	yellow
(2)	feeds	the	cats	daily

- What's wrong? Does the model capture these problems?

Beginning/end of sequence

- To capture behaviour at beginning/end of sequences, we can augment the input:

	w_{-1}	w_0	w_1	w_2	w_3	w_4	w_5
(1)	\<s\>	\<s\>	he	saw	the	yellow	\</s\>
(2)	\<s\>	\<s\>	feeds	the	cats	daily	\</s\>

- That is, assume $w_{-1} = w_0 =$ \<s\> and $w_{n+1} =$ \</s\> so:

$$P(\vec{w}) = \prod_{i=1}^{n+1} P(w_i | w_{i-2}, w_{i-1})$$

- Now, $P(\text{\</s\>} | \text{the, yellow})$ is low, indicating this is not a good sentence.

Beginning/end of sequence

- Alternatively, we could model all sentences as one (very long) sequence, including punctuation:

  two cats live in sam 's barn . sam feeds the cats daily . yesterday , he saw the yellow cat catch a mouse . [...]

- Now, trigrams like $P(.|\texttt{cats daily})$ and $P(,|\texttt{. yesterday})$ tell us about behavior at sentence edges.

- Here, all tokens are lowercased. What are the pros/cons of *not* doing that?

Practical details (2)

- Word probabilities are typically very small.

- Multiplying lots of small probabilities quickly gets so tiny we can't represent the numbers accurately, even with double precision floating point.

- So in practice, we typically use **negative log probabilities** (sometimes called **costs**):

  - Since probabilities range from 0 to 1, negative log probs range from 0 to ∞: *lower* cost = *higher* probability.
  - Instead of *multiplying* probabilities, we *add* neg log probabilities.

Interim Summary: N-gram probabilities

- "Probability of a sentence": how likely is it to occur in natural language? Useful in many natural language applications.

- We can never know the true probability, but we may be able to estimate it from corpus data.

- N-gram models are one way to do this:

  - To alleviate sparse data, assume word probs depend only on short history.
  - Tradeoff: longer histories may capture more, but are also more sparse.
  - So far, we estimated N-gram probabilites using MLE.

Interim Summary: Language models

- **Language models** tell us $P(\vec{w}) = P(w_1 \ldots w_n)$: *How likely to occur is this sequence of words?*

  Roughly: *Is this sequence of words a "good" one in my language?*

- LMs are used as a component in applications such as speech recognition, machine translation, and predictive text completion.

- To reduce sparse data, N-gram LMs assume words depend only on a fixed-length history, even though we know this isn't true.

Coming up next:

- Weaknesses of MLE and ways to address them (more issues with sparse data).

- How to evaluate a language model: are we estimating sentence probabilities accurately?

Evaluating a language model

- Intuitively, a trigram model captures more context than a bigram model, so should be a "better" model.

- That is, it should more accurately predict the probabilities of sentences.

- But how can we measure this?

Two types of evaluation in NLP

- **Extrinsic**: measure performance on a downstream application.

  - For LM, plug it into a machine translation/ASR/etc system.
  - The most reliable evaluation, but can be time-consuming.
  - And of course, we still need an evaluation measure for the downstream system!

- **Intrinsic**: design a measure that is inherent to the current task.

  - Can be much quicker/easier during development cycle.
  - But not always easy to figure out what the right measure is: ideally, one that correlates well with extrinsic measures.

Let's consider how to define an intrinsic measure for LMs.

Entropy

- Definition of the **entropy** of a random variable X:

  $$H(X) = \sum_x -P(x) \, \log_2 P(x)$$

- Intuitively: a measure of uncertainty/disorder

- Also: the expected value of $-\log_2 P(X)$

Entropy Example

One event (outcome)

$$P(a) = 1 \qquad\qquad H(X) = -1\log_2 1$$
$$= 0$$
Entropy Example

2 equally likely events:

$P(a) = 0.5$
$P(b) = 0.5$

$$H(X) = -0.5 \log_2 0.5 - 0.5 \log_2 0.5$$
$$= -\log_2 0.5$$
$$= 1$$
Entropy Example

4 equally likely events:

$$P(a) = 0.25$$
$$P(b) = 0.25$$
$$P(c) = 0.25$$
$$P(d) = 0.25$$

$$
\begin{aligned}
H(X) = & -0.25 \log_2 0.25 - 0.25 \log_2 0.25 \\
& -0.25 \log_2 0.25 - 0.25 \log_2 0.25 \\
= & -\log_2 0.25 \\
= & \ 2
\end{aligned}
$$

Entropy Example

$P(a) = 0.7$
$P(b) = 0.1$
$P(c) = 0.1$
$P(d) = 0.1$
3 equally likely events and one more likely than the others:

$$
\begin{aligned}
H(X) = & -0.7\log_2 0.7 - 0.1\log_2 0.1 \\
& -0.1\log_2 0.1 - 0.1\log_2 0.1 \\
= & -0.7\log_2 0.7 - 0.3\log_2 0.1 \\
= & -(0.7)(-0.5146) - (0.3)(-3.3219) \\
= & \; 0.36020 + 0.99658 \\
= & \; 1.35678
\end{aligned}
$$

Entropy Example

3 equally likely events and one much more likely than the others:

$$P(a) = 0.97$$
$$P(b) = 0.01$$
$$P(c) = 0.01$$
$$P(d) = 0.01$$
$$
\begin{aligned}
H(X) = &-0.97 \log_2 0.97 - 0.01 \log_2 0.01 \\
&-0.01 \log_2 0.01 - 0.01 \log_2 0.01 \\
= &-0.97 \log_2 0.97 - 0.03 \log_2 0.01 \\
= &-(0.97)(-0.04394) - (0.03)(-6.6439) \\
= &\ 0.04262 + 0.19932 \\
= &\ 0.24194
\end{aligned}
$$

$$H(X) = 0 \qquad H(X) = 1 \qquad H(X) = 2$$

$$H(X) = 3 \qquad H(X) = 1.35678 \qquad H(X) = 0.24194$$

Entropy as y/n questions

How many yes-no questions (bits) do we need to find out the outcome?

- Uniform distribution with 2^n outcomes: n q's.

- Other cases: entropy is the average number of questions per outcome in a (very) long sequence of outcomes, where questions can consider multiple outcomes at once.

Entropy as encoding sequences

- Assume that we want to encode a sequence of events X.

- Each event is encoded by a sequence of bits, we want to use as few bits as possible.

- For example

  - Coin flip: heads $= 0$, tails $= 1$
  - 4 equally likely events: a $= 00$, b $= 01$, c $= 10$, d $= 11$
  - 3 events, one more likely than others: a $= 0$, b $= 10$, c $= 11$
  - Morse code: e has shorter code than q

- Average number of bits needed to encode $X \geq$ entropy of X

The Entropy of English

- Given the start of a text, can we guess the next word?

- For humans, the measured entropy is only about 1.3.

  - Meaning: on average, given the preceding context, a human would need only 1.3 y/n questions to determine the next word.

  - This is an upper bound on the true entropy, which we can never know (because we don't know the true probability distribution).

- But what about N-gram models?

Cross-entropy

- Our LM estimates the probability of word sequences.

- A good model assigns high probability to sequences that actually have high probability (and low probability to others).

- Put another way, our model should have low uncertainty (entropy) about which word comes next.

- We can measure this using **cross-entropy**.

- Note that cross-entropy $\geq$ entropy: our model's uncertainty can be no less than the true uncertainty.

Computing cross-entropy

- For $w_1 \ldots w_n$ with large n, per-word cross-entropy is well approximated by:

$$H_M(w_1 \ldots w_n) = -\frac{1}{n} \log_2 P_M(w_1 \ldots w_n)$$

- This is just the average negative log prob our model assigns to each word in the sequence. (i.e., normalized for sequence length).

- Lower cross-entropy $\Rightarrow$ model is better at predicting next word.

Cross-entropy example

Using a bigram model from Moby Dick, compute per-word cross-entropy of I spent three years before the mast (here, without using end-of sentence padding):

$$
\begin{aligned}
-\tfrac{1}{7}(\quad & \lg_2(P(\mathit{I})) + \lg_2(P(\mathit{spent}|\mathit{I})) + lg_2(P(\mathit{three}|\mathit{spent})) + \lg_2(P(\mathit{years}|\mathit{three})) \\
& + \lg_2(P(\mathit{before}|\mathit{years})) + \lg_2(P(\mathit{the}|\mathit{before})) + \lg_2(P(\mathit{mast}|\mathit{the})) \quad) \\
= \quad -\tfrac{1}{7}(\quad & -6.9381 - 11.0546 - 3.1699 - 4.2362 - 5.0 - 2.4426 - 8.4246 \quad) \\
= \quad -\tfrac{1}{7}(\quad & 41.2660 \quad) \\
\approx \quad & 6
\end{aligned}
$$

- Per-word cross-entropy of the *unigram* model is about 11.

- So, unigram model has about 5 bits more uncertainty per word then bigram model. But, what does that mean?

Data compression

- If we designed an optimal code based on our bigram model, we could encode the entire sentence in about 42 bits.

- A code based on our unigram model would require about 77 bits.

- ASCII uses an average of 24 bits per word (168 bits total)!

- So better language models can also give us better data compression: as elaborated by the field of **information theory**.

Perplexity

- LM performance is often reported as **perplexity** rather than cross-entropy.

- Perplexity is simply $2^{\text{cross-entropy}}$

- The average branching factor at each decision point, if our distribution were uniform.

- So, 6 bits cross-entropy means our model perplexity is $2^6 = 64$: equivalent uncertainty to a uniform distribution over 64 outcomes.

Interpreting these measures

I measure the cross-entropy of my LM on some corpus as 5.2.
Is that good?

Interpreting these measures

I measure the cross-entropy of my LM on some corpus as 5.2.
Is that good?

- No way to tell! Cross-entropy depends on both the model and the corpus.

  - Some language is simply more predictable (e.g. casual speech vs academic writing).
  - So lower cross-entropy could mean the corpus is "easy", or the model is good.

- We can only compare different models on the same corpus.

- Should we measure on training data or held-out data? Why?

Sparse data, again

Suppose now we build a *trigram* model from Moby Dick and evaluate the same sentence.

- But $\mathrm{I\ spent\ three}$ never occurs, so $P_{MLE}(\mathrm{three\ |\ I\ spent}) = 0$

- which means the cross-entropy is infinite.

- Basically right: our model says $\mathrm{I\ spent\ three}$ should never occur, so our model is infinitely wrong/surprised when it does!

- Even with a unigram model, we will run into words we never saw before. So even with short N-grams, we need better ways to estimate probabilities from sparse data.

Smoothing

- The flaw of MLE: it estimates probabilities that make the training data maximally probable, by making everything else (unseen data) minimally probable.

- **Smoothing** methods address the problem by stealing probability mass from seen events and reallocating it to unseen events.

- Lots of different methods, based on different kinds of assumptions. We will discuss just a few.

Add-One (Laplace) Smoothing

- Just pretend we saw everything one more time than we did.

$$P_{\mathrm{ML}}(w_i|w_{i-2}, w_{i-1}) = \frac{C(w_{i-2}, w_{i-1}, w_i)}{C(w_{i-2}, w_{i-1})}$$

$$\Rightarrow \qquad P_{+1}(w_i|w_{i-2}, w_{i-1}) = \frac{C(w_{i-2}, w_{i-1}, w_i) + 1}{C(w_{i-2}, w_{i-1})} \qquad ?$$

Add-One (Laplace) Smoothing

- Just pretend we saw everything one more time than we did.

$$P_{\mathrm{ML}}(w_i|w_{i-2}, w_{i-1}) = \frac{C(w_{i-2}, w_{i-1}, w_i)}{C(w_{i-2}, w_{i-1})}$$

$$\Rightarrow \qquad P_{+1}(w_i|w_{i-2}, w_{i-1}) = \frac{C(w_{i-2}, w_{i-1}, w_i) + 1}{C(w_{i-2}, w_{i-1})} \qquad ?$$

- NO! Sum over possible w_i (in vocabulary V) must equal 1:

$$\sum_{w_i \in V} P(w_i|w_{i-2}, w_{i-1}) = 1$$

- If increasing the numerator, must change denominator too.

Add-one Smoothing: normalization

- We want:
$$\sum_{w_i \in V} \frac{C(w_{i-2}, w_{i-1}, w_i) + 1}{C(w_{i-2}, w_{i-1}) + x} = 1$$

- Solve for x:

$$\sum_{w_i \in V} (C(w_{i-2}, w_{i-1}, w_i) + 1) = C(w_{i-2}, w_{i-1}) + x$$

$$\sum_{w_i \in V} C(w_{i-2}, w_{i-1}, w_i) + \sum_{w_i \in V} 1 = C(w_{i-2}, w_{i-1}) + x$$

$$C(w_{i-2}, w_{i-1}) + v = C(w_{i-2}, w_{i-1}) + x$$

$$v = x$$

where $v =$ vocabulary size.

Add-one example (1)

- *Moby Dick* has one trigram that begins I spent (it's I spent in) and the vocabulary size is 17231.

- Comparison of MLE vs Add-one probability estimates:

	MLE	+1
$\hat{P}(\text{three} \mid \text{I spent})$	0	0.00006
$\hat{P}(\text{in} \mid \text{I spent})$	1	0.0001

- $\hat{P}(\text{in}\mid\text{I spent})$ seems very low, especially since in is a very common word. But can we find better evidence that this method is flawed?

Add-one example (2)

- Suppose we have a more common bigram w_1, w_2 that occurs 100 times, 10 of which are followed by w_3.

$$
\begin{array}{c|cc}
 & \text{MLE} & +1 \\
\hline
\hat{P}(w_3|w_1, w_2) & \frac{10}{100} & \frac{11}{17331} \\
 & & \approx 0.0006
\end{array}
$$

- Shows that the very large vocabulary size makes add-one smoothing steal *way* too much from seen events.

- In fact, MLE is pretty good for frequent events, so we shouldn't want to change these much.

Add-α (Lidstone) Smoothing

- We can improve things by adding $\alpha < 1$.

$$P_{+\alpha}(w_i|w_{i-1}) = \frac{C(w_{i-1}, w_i) + \alpha}{C(w_{i-1}) + \alpha v}$$

- Like Laplace, assumes we know the vocabulary size in advance.

- But if we don't, can just add a single "unknown" (UNK) item to the vocabulary, and use this for all unknown words during testing.

- Then: how to choose α?

Optimizing α (and other model choices)

- Use a three-way data split: **training** set (80-90%), **held-out** (or **development**) set (5-10%), and **test** set (5-10%)

  – Train model (estimate probabilities) on training set with different values of α

  – Choose the α that minimizes cross-entropy on development set

  – Report final results on test set.

- More generally, use dev set for evaluating different models, debugging, and optimizing choices. Test set simulates deployment, use it only once!

- Avoids overfitting to the training set and even to the test set.

Summary

- We can measure the relative goodness of LMs on the same corpus using cross-entropy: how well does the model predict the next word?

- We need smoothing to deal with unseen N-grams.

- Add-1 and Add-α are simple, but not very good.

Postscript

- There are better smoothing methods for N-gram language models, including one called **Kneser-Ney smoothing**.

- But neural network language models can do even better without a Markov assumption. (Later in the course.)
